HAL is a multi-disciplinary open access archive for the deposit and dissemination of scientific research documents, whether they are published or not. The documents may come from teaching and research institutions in France or abroad, or from public or private research centers.

L'archive ouverte pluridisciplinaire **HAL**, est destinée au dépôt et à la diffusion de documents scientifiques de niveau recherche, publiés ou non, émanant des établissements d'enseignement et de recherche français ou étrangers, des laboratoires publics ou privés.

A spatio-temporal hybrid Strauss hardcore point process for forest fire occurrences

Morteza Raeisi, Florent Bonneu, Edith Gabriel
LMA (Avignon University) & BioSP (INRAE)

July 11, 2021

Abstract

We propose a new point process model that combines, in the spatio-temporal setting, both multi-scaling by hybridization and hardcore distances. Our so-called hybrid Strauss hardcore point process model allows different types of interaction, at different spatial and/or temporal scales, that might be of interest in environmental and biological applications. The inference and simulation of the model are implemented using the logistic likelihood approach and the birth-death Metropolis-Hastings algorithm. Finally, we apply our model to forest fire occurrences in Spain.

1 Introduction

In point patterns, most types of interaction structure between points can be described by existing models. These models yield point patterns with mainly single-structure, but only a few with multi-structure. Interactions with single-structure are often classified into three classes: randomness, clustering and inhibition. Among inhibition processes is the hardcore process. It has some hardcore distance h in which distinct points are not allowed to come closer than a distance h apart. This type of interaction can be modelled by Gibbs point processes as the hardcore or Strauss hardcore point processes and also by Cox point processes as Matérn's hardcore (Matérn, 1960; 1986) or Matérn thinned Cox point processes (Andersen and Hahn, 2016). Here, we focus on the former, i.e. Gibbs models implemented by a hardcore component as in the Strauss hardcore model. The form of Strauss hardcore density indicates that the hardcore parameter only rules at least distance between points, and has no effect on the interaction terms of the density (Dereudre and Lavancier, 2017, sect. 2.3).

In several domains, there exist point patterns with hardcore distances that have to be modelled. Spatial point patterns with hardcore property can be found in capillaries studies (Mattfeldt et al., 2006; 2007; 2009), in texture synthesis (Hurtut et al., 2009), in forest fires (Turner, 2009), in cellular networks (Taylor et al., 2012 and Ying et al., 2014), in landslides (Das and Stein, 2016), in modern

and contemporary architecture and art (Stoyan, 2016) and in location clustering econometrics (Sweeney and Gomez-Antonio, 2016).

There also exist point patterns with either clustering and inhibition like hardcore interactions at different scales simultaneously (Badreldin et al., 2015; Andersen and Hahn, 2016 and Wang et al., 2020). Wang et al. (2020, sect. 2.4) investigated effect of the hardcore distance on spatial patterns of trees by comparing the pair correlation function curves for different values of hardcore distances in the fitted hybrid Geyer hardcore model. Raeisi et al. (2019) review spatial and spatio-temporal point processes that model both inhibition and clustering at different scales. Such multi-structure interactions can be modelled by the spatial hybrid Gibbs point process (Baddeley et al, 2013). In this paper, we aim to extend the spatial Strauss hardcore point process (Ripley, 1988) to the spatio-temporal framework and introduce a multi-scale version of it using hybridization approach. We use this model to describe one of the most complex phenomena from the spatio-temporal modeling point of view: forest fire occurrences.

The complexity of forest fire occurrences is due in particular to the existence of multi-scale structures and hardcore distances in space and time. For instance, changes in vegetation due to forest fires burnt areas affect the probability of fire occurrences during the regeneration period leading to the existence of hardcore distances in space-time. It can be also observed the multi-scale structure of clustering and inhibition in the spatio-temporal pattern of the forest fires as discussed in Gabriel et al. (2017). Wildfires have mainly been modelled by Cox processes and inferred by Bayesian hierarchical approaches, as the integrated nested Laplace approximation (INLA) approach (Rue et al., 2009). See Møller and Diaz-Avalos (2010), Pereira et al. (2013), Serra et al. (2012, 2014a,b), Najafabadi et al. (2015), Juan (2020) and Pimont et al. (2021) for single-structure models and Gabriel et al. (2017), Opitz et al. (2020) for multi-structure models. Recently, Raeisi et al. (2021) modelled the multi-structure of forest fire occurrences by a spatio-temporal Gibbs process and use a composite likelihood approach for its inference.

This paper is organized as follows. In Section 2 we introduce in the spatio-temporal framework the notations and definitions of Gibbs point processes in order to introduce our multi-scale version of the Strauss hardcore model. Section 3 is devoted to the inference of our model. It describes techniques to determine the irregular parameters (hardcore and interaction distances) and the logistic-likelihood approach generalized to the spatio-temporal setting to estimate the regular parameters. Section 4 illustrates the goodness-of-fit of the logistic likelihood approach on simulated patterns of our model obtained by an extended Metropolis-Hastings algorithm. Finally, we apply our model to a monthly forest fire data in the center of Spain in Section 5.

2 Towards multi-scale Strauss hardcore point processes

Gibbs models are flexible point processes that allow the specification of point interactions via a probability density defined with respect to the unit rate Poisson point process. These models allow to characterize a form of local or Markovian dependence amongst events. Gibbs point processes contain a large class of flexible and natural models that can be applied for:

- Postulating the interaction mechanisms between pairs of points,
- Taking into account clustering, randomness or inhibition structures,
- Combining several structures at different scales with the hybridization approach.

Let $\mathbf{x} = \{(\xi_1, t_1), \dots, (\xi_n, t_n)\}$ be a spatio-temporal point pattern where $(\xi_i, t_i) \in W = S \times T \subset \mathbb{R}^2 \times \mathbb{R}$. We consider $(W, d(\cdot, \cdot))$ where $d((u, v), (u', v')) := \max\{\|u - u'\|, |v - v'|\}$ for $(u, v), (u', v') \in W$ is a complete, separable metric space. The cylindrical neighbourhood $C_r^q(u, v)$ centred at $(u, v) \in W$ is defined by

$$C_r^q(u, v) = \{(a, b) \in W : \|u - a\| \leq r, |v - b| \leq q\}, \quad (1)$$

where $r, q > 0$ are spatial and temporal radius and $\|\cdot\|$ denotes the Euclidean distance in \mathbb{R}^2 and $|\cdot|$ denotes the usual distance in \mathbb{R} . Note that $C_r^q(u, v)$ is a cylinder with centre (u, v) , radius r , and height $2q$.

A finite Gibbs point process is a finite simple point process defined with a density $f(\mathbf{x})$ that satisfies the hereditary condition, i.e. $f(\mathbf{x}) > 0 \Rightarrow f(\mathbf{y}) > 0$ for all $\mathbf{y} \subset \mathbf{x}$.

A closely related concept to density functions is Papangelou conditional intensity function (Papangelou, 1974) which is a tool for simulating Gibbs models and inferring its parameters. The Papangelou conditional intensity of a spatio-temporal point process on W with density f is defined, for $(u, v) \in W$, by

$$\lambda((u, v)|\mathbf{x}) = \frac{f(\mathbf{x} \cup (u, v))}{f(\mathbf{x} \setminus (u, v))}, \quad (2)$$

with $a/0 := 0$ for all $a \geq 0$ (Cronie and van Lieshout, 2015).

The Papangelou conditional intensity is also very useful to describe the local interactions in a point pattern, and leads to the notion of a Markov point process which is the basis for the implementation of MCMC algorithms for simulations of Gibbs models. We say that the point process has "interactions of range R at (ξ, t) " if points further than R away from (ξ, t) do not contribute to the conditional intensity at (ξ, t) . A spatio-temporal Gibbs point process X has a finite interaction range R if the Papangelou conditional intensity satisfies

$$\lambda((u, v)|\mathbf{x}) = \lambda((u, v)|\mathbf{x} \cap C_R^R(u, v)) \quad (3)$$

for all configurations \mathbf{x} of X and all $(u, v) \in W$, where $C_R^R(u, v)$ denotes the cylinder of radius $R > 0$ and height $2R > 0$ centred at (u, v) . Spatio-temporal Gibbs models usually have finite interaction range property (spatio-temporal Markov property) and are called in this case Markov point processes (van Lieshout 2000). The finite range property of a spatio-temporal Gibbs model implies that the probability to insert a point (u, v) into \mathbf{x} depends only on some cylindrical neighborhood of (u, v) .

Here, we first review spatio-temporal Gibbs models and then extend the spatial Strauss hardcore model to the spatio-temporal and multi-scale context. We further refer to Dereudre (2019) for more formal introduction of Gibbs point processes.

2.1 Single-scale Gibbs point process models

In the literature, several spatio-temporal Gibbs point process models have been proposed such as the hardcore (Cronie and van Lieshout, 2015), Strauss (Gonzalez et al., 2016), area-interaction (Iftimi et al., 2018), and Geyer (Raeisi et al., 2021) point processes.

A Gibbs point process model explicitly postulates that interactions traduce dependencies between the points of the pattern. The hardcore interaction is one of the simplest type of interaction, which forbids points being too close to each other. The homogeneous spatio-temporal hardcore point process is defined by the density

$$f(\mathbf{x}) = c\lambda^{n(\mathbf{x})}\mathbb{1}\{|\xi - \xi'| > h_s \text{ or } |t - t'| > h_t; \forall (\xi, t) \neq (\xi', t') \in \mathbf{x}\}, \quad (4)$$

with respect to a unit rate Poisson point process on W , where $c > 0$ is a normalizing constant, $\lambda > 0$ is an activity parameter, $h_s, h_t > 0$ are, respectively, the spatial and the temporal hardcore distances and $n(\mathbf{x})$ is the number of points in \mathbf{x} . The Papangelou conditional intensity of a homogeneous spatio-temporal hardcore point process for $(u, v) \notin \mathbf{x}$ is obtained

$$\begin{aligned} \lambda((u, v)|\mathbf{x}) &= \lambda\mathbb{1}\{|\xi - u| > h_s \text{ or } |t - v| > h_t; \forall (\xi, t) \in \mathbf{x}\} \\ &= \lambda \prod_{(\xi, t) \in \mathbf{x}} \mathbb{1}\{|\xi - u| > h_s \text{ or } |t - v| > h_t\} \\ &= \lambda \prod_{(\xi, t) \in \mathbf{x}} \mathbb{1}\{(\xi, t) \notin C_{h_s}^{h_t}(u, v)\}. \end{aligned} \quad (5)$$

The homogeneous spatio-temporal Strauss point process is defined by density

$$f(\mathbf{x}) = c\lambda^{n(\mathbf{x})}\gamma^{S_r^q(\mathbf{x})}, \quad (6)$$

with respect to a unit rate Poisson point process on W , where

$$S_r^q(\mathbf{x}) = \sum_{(\xi, t) \neq (\xi', t') \in \mathbf{x}} \mathbb{1}\{|\xi - \xi'| \leq r, |t - t'| \leq q\}$$

and the Papangelou conditional intensity of the model is

$$\text{for } (u, v) \notin \mathbf{x}, \quad \lambda((u, v)|\mathbf{x}) = \lambda \gamma^{n[C_r^q(u, v); \mathbf{x}]}, \quad (7)$$

and

$$\text{for } (\xi, t) \in \mathbf{x}, \quad \lambda((\xi, t)|\mathbf{x}) = \lambda \gamma^{n[C_r^q(\xi, t); \mathbf{x} \setminus (\xi, t)]}, \quad (8)$$

where $n[C_r^q(y, z); \mathbf{x}] = \sum_{(\xi, t) \in \mathbf{x}} \mathbb{1}\{\|y - \xi\| \leq r, |z - t| \leq q\}$ is the number of points in \mathbf{x} which are in a cylinder $C_r^q(y, z)$. Although the Strauss point process was originally intended as a model of clustering, it can only be used to model inhibition, because the parameter γ cannot be greater than 1. If we take $\gamma > 1$, the density function of Strauss model is not integrable, so it does not define a valid probability density.

As mentioned, Strauss point process model only achieves the inhibition structure. In spatial framework, two ways are introduced to overcome this problem that we extend to spatio-temporal framework hence defining two new spatio-temporal Gibbs point process models.

A first way is to consider an upper bound for the number of neighboring points that interact. In this case, Raeisi et al. (2021) defined a homogeneous spatio-temporal Geyer saturation point process by density

$$f(\mathbf{x}) = c \lambda^{n(\mathbf{x})} \prod_{(\xi, t) \in \mathbf{x}} \gamma^{\min\{s, n^*[C_r^q(\xi, t); \mathbf{x}]\}}, \quad (9)$$

with respect to a unit rate Poisson point process on W , where s is a saturation parameter and $n^*[C_r^q(\xi, t); \mathbf{x}] = n[C_r^q(\xi, t); \mathbf{x} \setminus (\xi, t)] = \sum_{(u, v) \in \mathbf{x} \setminus (\xi, t)} \mathbb{1}\{\|u - \xi\| \leq r, |v - t| \leq q\}$.

A second way is to introduce a hardcore condition to the Strauss density (6). Hence, we can define a Strauss hardcore model in spatio-temporal context.

Definition 1. We define the *spatio-temporal Strauss hardcore point process* as the point process with density

$$f(\mathbf{x}) = c \lambda^{n(\mathbf{x})} \gamma^{S_r^q(\mathbf{x})} \mathbb{1}\{\|\xi - \xi'\| > h_s \text{ or } |t - t'| > h_t; \forall (\xi, t) \neq (\xi', t') \in \mathbf{x}\}, \quad (10)$$

where $0 < h_s < r$ and $0 < h_t < q$.

The model could be used to model clustering patterns with a softer attraction between the points like a pattern with a combination of interaction terms that show repulsion between the points at a small scale and attraction between the points at a larger scale. The Papangelou conditional intensity of a homogeneous spatio-temporal Strauss hardcore point process for $(u, v) \notin \mathbf{x}$ is obtained

$$\begin{aligned} \lambda((u, v)|\mathbf{x}) &= \lambda \gamma^{n[C_r^q(u, v); \mathbf{x}]} \mathbb{1}\{\|\xi - u\| > h_s \text{ or } |t - v| > h_t; \forall (\xi, t) \in \mathbf{x}\} \\ &= \lambda \gamma^{n[C_r^q(u, v); \mathbf{x}]} \prod_{(\xi, t) \in \mathbf{x}} \mathbb{1}\{(\xi, t) \notin C_{h_s}^{h_t}(u, v)\}. \end{aligned} \quad (11)$$

We can define inhomogeneous versions of all above models by replacing the constant λ by a function $\lambda(\xi, t)$, inside the product operator over $(\xi, t) \in \mathbf{x}$, that expresses a spatio-temporal trend, which can be a function of the coordinates of the points and depends on covariate information.

2.2 Multi-scale Gibbs point process models

Since most natural phenomena exhibit dependence at multiple scales as earthquake (Siino et al., 2017;2018) and forest fire occurrences (Gabriel et al., 2017), single-scale Gibbs point process models are unrealistic in many applications. This motivates us and other statisticians to construct multi-scale generalizations of the classical Gibbs models. Baddeley et al. (2013) proposed hybrid models as a general way to generate multi-scale processes combining Gibbs processes. Given m densities f_1, f_2, \dots, f_m of Gibbs point processes, the hybrid density is defined as $f(\mathbf{x}) = cf_1(\mathbf{x}) \times f_2(\mathbf{x}) \times \dots \times f_m(\mathbf{x})$ where c is a normalization constant.

Iftimi et al. (2018) extended the hybrid approach for an area-interaction model in spatio-temporal framework where the density is given by

$$f(\mathbf{x}) = c \prod_{(\xi,t) \in \mathbf{x}} \lambda(\xi,t) \prod_{j=1}^m \gamma_j^{-\ell(\cup_{(\xi,t) \in \mathbf{x}} C_{r_j}^{q_j}(\xi,t))}, \quad (12)$$

with respect to a unit rate Poisson process on W , where (r_j, q_j) are pairs of irregular parameters of the model and γ_j are interaction parameters, $j = 1, \dots, m$.

In the same way, Raesi et al. (2021) defined a spatio-temporal multi-scale Geyer saturation point process with density

$$f(\mathbf{x}) = c \prod_{(\xi,t) \in \mathbf{x}} \lambda(\xi,t) \prod_{j=1}^m \gamma_j^{\min\{s_j, n(C_{r_j}^{q_j}(\xi,t); \mathbf{x})\}} \quad (13)$$

with respect to a unit rate Poisson process on W , where $c > 0$ is a normalizing constant, $\lambda \geq 0$ is a measurable and bounded function, $\gamma_j > 0$ are the interaction parameters.

Similarly, a hybrid version of spatio-temporal Strauss model can be defined by hybridization.

Definition 2. We define the *spatio-temporal hybrid Strauss point process* with density

$$f(\mathbf{x}) = c \prod_{(\xi,t) \in \mathbf{x}} \lambda(\xi,t) \prod_{j=1}^m \gamma_j^{S_{r_j}^{q_j}(\mathbf{x})}, \quad (14)$$

with respect to a unit rate Poisson process on $W = S \times T$.

Note that we called the model (14) hybrid rather than multi-scale. The model (14) can cover inhibition structure because $0 < \gamma_j < 1, \forall j \in \{1, \dots, m\}$. However, it can take into account clustering if one of densities in hybrid is the one of a hardcore process.

2.3 Hybrid Strauss hardcore point process

The hybrid Gibbs point process models do not necessarily include m same Gibbs point process models (see Baddeley et al., 2015 sect. 13.8). Badreldin et al.

(2015) applied a spatial hybrid model including a hardcore density to model strong inhibition at very short distances, Geyer density for cluster structure in short to medium distances and a Strauss density for a randomness structure in larger distances to the spatial pattern of the halophytic species distribution in an arid coastal environment. Wang et al. (2020) fitted a spatial hybrid Geyer hardcore point process on the tree spatial distribution patterns. In this section, we extend this type of hybrids to the spatio-temporal context.

Definition 3. We define the *spatio-temporal hybrid Strauss hardcore point process* with density

$$f(\mathbf{x}) = c \prod_{(\xi, t) \in \mathbf{x}} \lambda(\xi, t) \prod_{j=1}^m \gamma_j S_{r_j}^{q_j}(\mathbf{x}) \times \mathbb{1}\{\|\xi' - \xi''\| > h_s \text{ or } |t' - t''| > h_t; \forall (\xi', t') \neq (\xi'', t'') \in \mathbf{x}\}, \quad (15)$$

where $0 < h_s < r_1 < \dots < r_m$ and $0 < h_t < q_1 < \dots < q_m$.

In the same way, Papangelou conditional intensity of an inhomogeneous spatio-temporal hybrid Strauss hardcore process for $(u, v) \notin \mathbf{x}$ is obtained

$$\begin{aligned} \lambda((u, v)|\mathbf{x}) &= \lambda(u, v) \prod_{j=1}^m \gamma_j^{n[C_{r_j}^{q_j}(u, v); \mathbf{x}]} \mathbb{1}\{\|\xi - u\| > h_s \text{ or } |t - v| > h_t; \forall (\xi, t) \in \mathbf{x}\} \\ &= \lambda(u, v) \prod_{j=1}^m \gamma_j^{n[C_{r_j}^{q_j}(u, v); \mathbf{x}]} \prod_{(\xi, t) \in \mathbf{x}} \mathbb{1}\{(\xi, t) \notin C_{h_s}^{h_t}(u, v)\}. \end{aligned} \quad (16)$$

The conditional intensity of the Gibbs point process models including a hardcore interaction term takes the value zero at some locations. We can thus write that for all parameters of the model

$$\lambda((u, v)|\mathbf{x}) = m((u, v)|\mathbf{x}) \lambda^+((u, v)|\mathbf{x}), \quad (17)$$

where $m((u, v)|\mathbf{x})$ takes only the values 0 and 1, and $\lambda^+((u, v)|\mathbf{x}) > 0$ everywhere.

In the same way as Iftimi et al. (2018) and Raeisi et al. (2021), the spatio-temporal hybrid Strauss hardcore point process (15) is a Markov point process in Ripley-Kelly's (1977) sense at interaction range $\max\{r_m, q_m\}$.

3 Inference

Gibbs point process models involve two types of parameters: regular parameters and irregular parameters. A parameter is called regular if the log likelihood of density is a linear function of that parameter otherwise it is called irregular. Typically, regular parameters determine the 'strength' of the interaction, while irregular parameters determine the 'range' of the interaction. As an example,

in the Strauss hardcore point process (10), the trend parameter λ and the interaction γ are regular parameters and the interaction distances r and q and the hardcore distances h_s and h_t are irregular parameters.

To determine the interaction distances r and q , there are several practical techniques, but no general statistical theory available. A useful technique is the maximum profile pseudo-likelihood approach (Baddeley and Turner, 2000). In the spatio-temporal framework, Iftimi et al. (2018) and Raeisi et al. (2021) selected feasible range of irregular parameters by analyzing the behavior of some summary statistics and the goodness-of-fit of several models with different combinations of parameters.

The hardcore interaction term $m(\cdot|\mathbf{x})$ in the conditional intensity (17) does not depend on the other parameters of the densities of Gibbs point processes. This implies that it can first be estimated and kept fixed for the sequel (Baddeley et al., 2019, p. 26). In the spatial framework, the maximum likelihood estimate of the hardcore distance in $m(\cdot|\mathbf{x})$ corresponds to the minimum interpoint distance (Baddeley et al., 2013, Lemma 7). The generalization to the spatio-temporal context with a cylindrical hardcore structure implies to consider a multi-objective minimization problem over the spatial and temporal hardcore distances h_s and h_t . The choice of our hardcore parameters needs to analyze the Pareto front of feasible solutions on the graph of spatial and temporal interpoint distances. We refer the reader to Ehrhoff (2005) for a description of multi-criteria optimization and the definition of Pareto optimality. To estimate the hardcore distance h_s and h_t , we consider a feasible solution on the Pareto front as large as possible and with a ratio consistent with our knowledge of interaction mechanisms in practice.

Regular parameters can be estimated using the pseudo-likelihood method (Baddeley and Turner, 2000) or logistic likelihood method (Baddeley et al., 2014) rather than the maximum likelihood method (Ogata and Tanemura, 1981). Due to the advantage of the logistic likelihood over pseudo-likelihood for spatio-temporal Gibbs point processes (Iftimi et al., 2018; Raeisi et al., 2021), we implement the former approach in Raeisi et al. (2021, *Algorithm 2*) for regular parameter estimation of the spatio-temporal hybrid Strauss hardcore point process.

We assume that $\boldsymbol{\theta} = (\log \gamma_1, \log \gamma_2, \dots, \log \gamma_m)$ is the logarithm of interaction parameters in spatio-temporal hybrid Strauss hardcore point process (15). The Papangelou conditional intensity of the spatio-temporal hybrid Strauss hardcore process is, for $(u, v) \in W$ and $\forall(\xi, t) \in \mathbf{x} \setminus (u, v)$,

$$\lambda((u, v)|\mathbf{x}) = \lambda(u, v) \prod_{j=1}^m \gamma_j^{n[C_{r_j}^{q_j}(u, v); \mathbf{x} \setminus (u, v)]} \mathbb{1}_{\{||\xi - u|| > h_s \text{ or } |t - v| > h_t\}}. \quad (18)$$

To estimate $\boldsymbol{\theta}$, due to (17), we just consider the points (u, v) where $m((u, v)|\mathbf{x})$ is equal to 1 in (18). By defining $S_j((u, v), \mathbf{x}) := n[C_{r_j}^{q_j}(u, v); \mathbf{x} \setminus (u, v)]$ in (18), we can thus write $\lambda_{\boldsymbol{\theta}}((u, v)|\mathbf{x}) = \lambda(u, v) \prod_{j=1}^m \exp(\theta_j S_j((u, v), \mathbf{x}))$. Hence, the logarithm of the Papangelou conditional intensity of the spatio-temporal hybrid Strauss hardcore point process for $(u, v) \in W$ which satisfies in hardcore

condition, i.e. $m((u, v)|\mathbf{x}) = 1$ in (18), is

$$\begin{aligned}\log \lambda((u, v)|\mathbf{x}) &= \log \lambda(u, v) + \sum_{j=1}^m (\log \gamma_j) S_j((u, v), \mathbf{x}) \\ &= \log \lambda(u, v) + \boldsymbol{\theta}^\top \mathbf{S}((u, v), \mathbf{x})\end{aligned}\tag{19}$$

corresponding to a linear model in $\boldsymbol{\theta}$ with offset $\log \lambda(u, v)$ where $\mathbf{S}((u, v), \mathbf{x}) = [S_1((u, v), \mathbf{x}), S_2((u, v), \mathbf{x}), \dots, S_m((u, v), \mathbf{x})]^\top$ is a sufficient statistics.

By considering a set of dummy points \mathbf{d} from an independent Poisson process with intensity function ρ , we obtain by defining the Bernoulli variables $Y((\xi, t)) = \mathbb{1}_{\{(\xi, t) \in \mathbf{x}\}}$ for $(\xi, t) \in \mathbf{x} \cup \mathbf{d}$ that the logit of $P(Y((\xi, t))) = 1$ is equal to $\log \frac{\lambda_{\boldsymbol{\theta}}((\xi, t)|\mathbf{x}) \rho(\xi, t)}{\rho(\xi, t)}$. Under regularity conditions, the log-logistic likelihood

$$\begin{aligned}\log LL(\mathbf{x}, \mathbf{d}; \boldsymbol{\theta}) &= \sum_{(\xi, t) \in \mathbf{x}} \log \frac{\lambda_{\boldsymbol{\theta}}((\xi, t)|\mathbf{x})}{\lambda_{\boldsymbol{\theta}}((\xi, t)|\mathbf{x}) + \rho(\xi, t)} \\ &\quad + \sum_{(\xi, t) \in \mathbf{d}} \log \frac{\rho(\xi, t)}{\lambda_{\boldsymbol{\theta}}((\xi, t)|\mathbf{x}) + \rho(\xi, t)},\end{aligned}\tag{20}$$

admits a unique maximum. By consequence, the estimation of $\boldsymbol{\theta}$ in the Papangelou conditional intensity is equivalent to the estimation of logistic regression parameters, already implemented by using standard software for GLMs. The logistic regression

$$\log \frac{\lambda_{\boldsymbol{\theta}}((\xi, t)|\mathbf{x})}{\rho(\xi, t)} = \log \frac{\lambda(\xi, t)}{\rho(\xi, t)} + \sum_{j=1}^m \theta_j S_j((\xi, t), \mathbf{x}),\tag{21}$$

is a linear model in $\boldsymbol{\theta}$ with offset $\log \frac{\lambda(\xi, t)}{\rho(\xi, t)}$. We use the approach of Raeisi et al. (2021) for data and dummy points such that $m(\cdot|\mathbf{x}) = 1$. We also consider that $\lambda(\xi, t) = \beta \mu(\xi, t)$, where $\mu(\xi, t)$ is a trend preliminary estimated with spatio-temporal covariates.

4 Simulation study

Due to the markovian property of the spatio-temporal hybrid Strauss hardcore point process (15), its Papangelou conditional intensity at a point thus depends only on that point and its neighbors in \mathbf{x} . Hence, We can design simulation approach by Markov chain Monte Carlo algorithms.

Gibbs point process models can be simulated a birth-death Metropolis-Hastings algorithm that typically requires only computation of the Papangelou conditional intensity (Møller and Waagepetersen, 2004). Raeisi et al. (2021) extended the birth-death Metropolis-Hastings algorithm to the spatio-temporal context that we adapt here for simulating the spatio-temporal hybrid Strauss hardcore point process.

Table 1: Parameter combinations of three hybrid Strauss hardcore point process models used in simulation study.

Model	Values of parameter			
	Regular parameters		Irregular parameters	
	λ	γ	r, q	h_s, h_t
<i>Model 1</i>	70	(0.8,.08)	(0.05,0.1)	(0.01,0.01)
<i>Model 2</i>	50	(1.5,1.5)	(0.05,0.1)	(0.01,0.01)
<i>Model 3</i>	70	(0.5,1.5)	(0.05,0.1)	(0.01,0.01)

Table 2: Mean and 95% interval regular parameter estimates of the three hybrid Strauss hardcore point process models used in simulation study.

True values	Mean	95% CI
<i>Model 1</i>		
$\lambda = 70$	71.43	(69.16,73.70)
$\gamma_1 = 0.8$	0.89	(0.78,1.00)
$\gamma_2 = 0.8$	0.78	(0.74,0.82)
<i>Model 2</i>		
$\lambda = 50$	50.84	(48.99,52.68)
$\gamma_1 = 1.5$	1.41	(1.23,1.60)
$\gamma_2 = 1.5$	1.46	(1.38,1.54)
<i>Model 3</i>		
$\lambda = 70$	71.67	(69.18,74.15)
$\gamma_1 = 0.5$	0.50	(0.43,0.57)
$\gamma_2 = 1.5$	1.49	(1.42,1.55)

We implement the estimation and simulation algorithms in R (R Core Team, 2016) and generate simulations of three stationary spatio-temporal hybrid Strauss hardcore point processes specified by a conditional intensity of the form (18) in $W = [0, 1]^3$. The parameter values used for the simulations are reported in Table 1. The spatial and temporal radii r and q , spatial and temporal hardcores h_s and h_t , are treated as known parameters.

We generate 100 simulations of each specified model. Boxplots of parameter estimates λ , γ_1 , and γ_2 obtained from the logistic likelihood estimation method for each model are shown in Figure 1. The red horizontal lines represent the true parameter values. Point and interval parameter estimates λ , γ_1 , and γ_2 are reported in Table 2. Most of the estimated parameter values are close to the true values for three models. Due to visual and computational comparisons, we conclude that the logistic likelihood approach performs well for spatio-temporal hybrid Strauss hardcore point processes.

5 Application

In this section we aim to model the interactions of forest fire occurrences across a range of spatio-temporal scales.

Figure 1: Boxplots of regular parameter estimates of the hybrid Strauss hardcore point process obtained from the logistic likelihood estimation methods. Up to down: *Model 1*, *Model 2*, and *Model 3*

Figure 2: Left: Map of region of Castilla-La Mancha (Spain). Middle: Forest fire locations. Right: monthly numbers of fires recorded between January 2004 and December 2007 with burnt areas, spatial distances and time distances respectively bigger than 5 *ha*, 0.2 *km* and 100 *days*.

5.1 Data description

The `clmfires` dataset available in `spatstat` package records the occurrence of forest fires in the region of Castilla-La Mancha, Spain (Figure 2, left) from 1998 to 2007. The study area is approximately 400 by 400 *km*. The `clmfires` dataset has already been used in some academic works devoted to the point process theory (see e.g. Juan et al., 2010; Gomez-Rubio, 2020, sect. 7.4.2; Myllymäki et al., 2020). The dataset has two levels of precision: from 1998 to 2003 locations were recorded as the centroids of the corresponding “district units”, while since 2004 locations correspond to the exact UTM coordinates of the fire occurrences.

Due to the low precision of fire locations for the years 1998 to 2003 (Gomez-Rubio 2020, sect. 7.4.2), we focus on fires between 2004 and 2007. In this period, we consider large forest fires with burnt areas larger than 5 *ha*. Figure 2 (middle) shows the point pattern of 432 wildfire locations onto the spatial region.

Due to memory constraints and availability of climate covariates in months, we consider monthly fire occurrences. The temporal component of the process takes integer values from 1 to 48. We thus consider $W = S \times T$ where S is the region of Castilla-la-Mancha and $T = \{1, 2, \dots, 48\}$ corresponds to the months since January 2004. Figure 2 (right) shows the monthly number of fires occurring during our time period. We observe seasonal effects with notably large numbers of fires in summer that could be caused by high temperatures and low precipitations in this period and also by human activities.

In point pattern analysis, the spatial (spatio-temporal) inhomogeneity of patterns is notably driven by covariates. The `clmfires` dataset contains four environmental covariates that we include in our analysis: *elevation*, *orientation*, *slope* and *land use*. The covariates are known on a spatial grid with pixels of 4×4 *km*, resulting in a total of 10000 pixels. The *land use* is a factor-valued covariate whereas the others are real-valued covariates. We also consider weather data freely provided by the *WorldClim* database¹ and containing monthly max-

¹<https://www.worldclim.org>

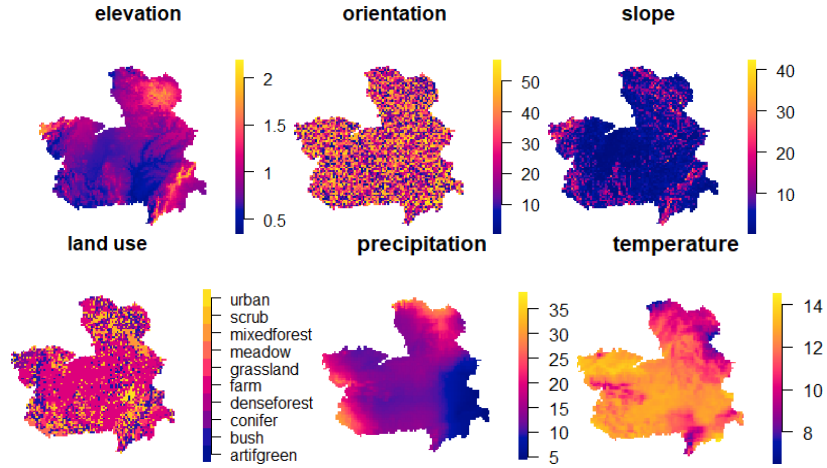

Figure 3: Image plot of environmental covariates (*elevation*, *orientation*, *slope* and *land use*) and climate covariates (*precipitation* and *temperature*) in January 2007.

imum temperatures ($^{\circ}C$) and total precipitations (mm). Figure 3 illustrates the environmental covariates, which are considered fixed during our temporal period, and the climate covariates in January 2007.

5.2 Estimation

First, we estimate the trend function by considering a generalized linear model (GLM) on covariates. Then, by an exploratory analysis using spatio-temporal summary statistics we approximate the hardcore parameters and the interaction ranges. Finally, we use the logistic likelihood approach described in Section 3 for the estimation of regular parameters of our model with the trend function estimated in the preliminary step.

5.2.1 Trend estimate

Since covariates are available on a spatial grid, we restrict our attention on the related grid centers $\xi_i, i = 1, \dots, 10000$ and months $\{t_j\}_{j=1, \dots, 48} \in T$ and consider $N_{ij} | \lambda(\xi_i, t_j) \sim Poisson(\lambda(\xi_i, t_j))$ where N_{ij} is the number of forest fires in the i^{th} grid center at month t_j .

Following Raeisi et al. (2021), by considering a GLM with Poisson response, we obtain:

$$\log \lambda(\xi_i, t_i) = \beta_0 + \sum_{k=1}^6 \beta_k Z_k(\xi_i, t_i), \quad (22)$$

where $Z_k(\xi_i, t_i)$, $k = 1, \dots, 6$, are the environmental and climatic covariates at point (ξ_i, t_i) and $\beta_0, \beta_k, k = 1, \dots, 6$ are the coefficients to estimate. As said before, we consider the same values for environmental covariates over time. A

Table 3: Estimated coefficients, standard errors and p -values based on two-tailed Student’s t -tests of significant differences from zero.

Coefficients	Estimate	Standard error	p -value
β_0 (intercept)	-8.468	0.298	$< 2 \times 10^{-16}$ ***
β_1 (elevation)	0.546	0.164	0.001 ***
β_2 (orientation)	0.005	0.003	0.114
β_3 (slope)	-0.019	0.01	0.054
β_4 (land use)	-0.009	0.024	0.689
β_5 (precipitation)	-0.007	0.002	0.003 **
β_6 (temperature)	0.054	0.006	$< 2 \times 10^{-16}$ ***

straightforward way to fit a GLM in R is to use the function `glm`. Table 3 reports the estimated coefficients in (22) and their significance level by a two-tailed Student’s t -test. Coefficients higher (respectively lower) than zero imply an increase (resp. decrease) of the expected mean number of forest fires when the covariate value increase (resp. decrease). Those related to *elevation* and *temperature* are positively significant, showing that these two covariates favors the ignition of wildfires. At the opposite, the covariate *precipitation* has a negative significant coefficient indicating that an increase of the amount of precipitation induces a decrease in the mean number of forest fires. The *land use* appears not significantly different from zero, it can be explained by the low spatial resolution of the covariates.

5.2.2 Irregular parameter estimates

We have two types of irregular parameters in our spatio-temporal Gibbs point process. On the one hand, the hardcore distances that we can choose among the feasible solutions on the Pareto front of spatial and temporal interpoint distances. According to Figure 4, we choose on the Pareto front the unique feasible solution in our case that gives non-zero values for the two hardcore distances, i.e. $h_s = 0.35 \text{ km}$ and $h_t = 1 \text{ month}$. On the other hand, for the nuisance parameters m , r_j and q_j , $j = 1, \dots, m$, there is no common method for estimating them. Here we considered several combinations of ad-hoc values within a reasonable range and select the optimal irregular parameters according to the Akaike’s Information Criterion (AIC) of the fitted model after the regular parameter estimation step (Raeisi et al., 2021). We chose 25 configurations of reasonable range for the nuisance parameters using a preliminary spatio-temporal exploratory analysis of the interaction ranges done with the inhomogeneous pair correlation function, the maximum nearest neighbor distance and the temporal auto-correlation function. We fitted the spatio-temporal hybrid Strauss point process model for a range of ad-hoc values $r_j \in (0.35, 20]$, $q_j \in \{2, \dots, 15\}$, $j = 1, \dots, m$ and $m \in \{1, \dots, 6\}$. The minimum AIC is obtained for the combination given in Table 4.

Figure 4: Spatial and temporal interpoint distances respectively lower than 5 kms and 12 months (black circles). The red line corresponds to the Pareto front and the red rectangle to the hardcore domain.

Table 4: Parameter estimates for $m = 6$.

	Irregular parameters					
r	0.5	1	1.5	6	15	20
q	2	4	6	8	12	15
Estimated regular parameters						
	$\hat{\gamma}_1 = 2.56$	$\hat{\gamma}_2 = 2.24$	$\hat{\gamma}_3 = 4.65$	$\hat{\gamma}_4 = 0.88$	$\hat{\gamma}_5 = 1.17$	$\hat{\gamma}_6 = 0.81$

5.2.3 Regular parameter estimates

We consider the logistic likelihood method investigated in Section 3 to estimate the regular parameters. We simulate dummy points from an inhomogeneous Poisson point process with intensity $\rho(\xi, t) = C\hat{\lambda}(\xi, t)/\nu$ where $C = 4$ by a classical rule of thumb in the logistic likelihood approach, $\hat{\lambda}$ is the estimated trend and $\nu = 4 \times 4 \times 1$ is the volume of a grid cell on one month. In order to satisfy the hardcore condition in (17), we remove dummy points at spatial and temporal distances respectively less than h_s and h_t . Estimated regular parameters are provided in Table 4.

5.3 Goodness-of-fit

The goodness-of-fit is accomplished by simulating point patterns from the fitted model. The first diagnostic can be formulated by summary statistics of point processes. As the second-order characteristics carry most of the information on the spatio-temporal structure (Stoyan, 1992 ; Gonzalez et al., 2016), we only consider the pair correlation function (g -function).

We generate $n_{sim} = 99$ simulations from the fitted hybrid Strauss hardcore

model and compute the corresponding second-order summary statistics $g_i(u, v)$, $i = 1, \dots, n_{sim}$, for fixed spatio-temporal distances (u, v) . We then build upper and lower envelopes:

$$U(u, v) = \max_{1 \leq i \leq n_{sim}} g_i(u, v), \quad L(u, v) = \min_{1 \leq i \leq n_{sim}} g_i(u, v), \quad (23)$$

and compare the summary statistics obtained from the data, $g_{obs}(u, v)$, to the pointwise envelopes. If it lies outside the envelopes at some spatio-temporal distances (u, v) , then we reject at these distances the hypothesis that our data come from our fitted model. Figure 5 shows the spatio-temporal inhomogeneous g -function computed on our dataset (blue) and the envelopes obtained from the fitted model (light grey); $g_{obs}(u, v)$ lies inside the envelopes for all (u, v) , meaning that the hybrid Strauss hardcore model is suitable for the data.

Figure 5: Envelopes of the spatio-temporal inhomogeneous g -function obtained from simulations of the fitted spatio-temporal hybrid Strauss hardcore point process (light grey). The blue surface corresponds to g_{obs} . Temporal separations are in *month* and spatial distances are in *kilometer*.

In addition, we compute global envelopes and p -value of the spatio-temporal g -functions based on the Extreme Rank Length (ERL) measure defined in Myllymäki et al. (2017) and implemented in the R package GET (Myllymäki and Mrkvička, 2020). For each point pattern, we consider the long vector T_i , $i = 1, \dots, n_{sim}$ (resp. T_{obs}) merging the $g_i(\cdot, v)$ (resp. $g_{obs}(\cdot, v)$) estimates for all considered values h_t . The ERL measure of vector T_i (resp. T_{obs}) of length n_{st} is defined as

$$E_i = \frac{1}{n_{ns}} \sum_{j=1}^{n_{st}} \mathbb{1}\{R_j \prec R_i\},$$

where R_i is the vector of pointwise ordered ranks and \prec is an ordering operator (Myllymäki et al., 2017; Myllymäki and Mrkvička, 2020). The final p -value is obtained by

$$p_{erl} = \frac{1 + \sum_{i=1}^{n_{sim}} \mathbb{1}\{E_i \geq E_{obs}\}}{n_{sim} + 1}.$$

Due to the global p -value $p_{erl} = 0.59$ and the absence of significant regions, that corresponds here to pairs of spatial and temporal distances where the statistics

is significantly above or below the envelopes (see Figure 6 and GET package), we conclude that our hybrid Strauss hardcore model can not be rejected a significance level of 1%.

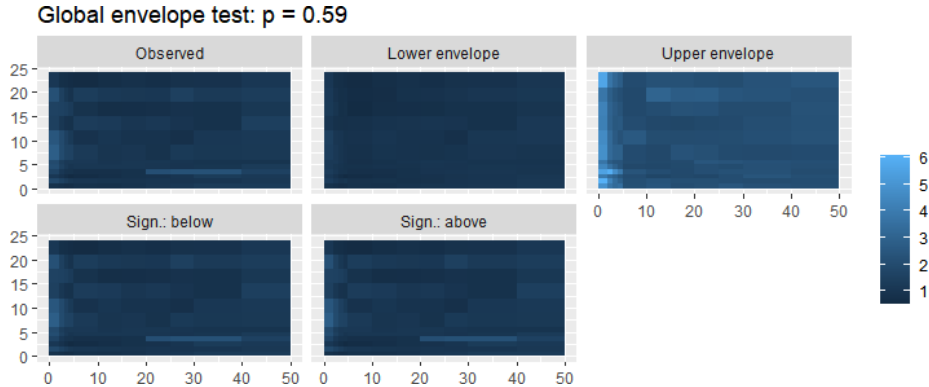

Figure 6: Top: estimated pair correlation function \hat{g}_{obs} , lower E_L and upper E_U bounds of the 99% global rank envelope (ERL). Bottom: differences $E_{obs} - E_L$ and $E_U - E_{obs}$. Negative values (if any) are represented in red and lead to reject the fitted model. Values on the horizontal axis are in kilometers and those on the vertical axis are in months.

Conclusion

In this paper, we introduced the spatio-temporal Strauss hardcore point process. The Strauss hardcore model is a Gibbs model for which points are pushed to be at a hardcore distance apart and repel up to an interaction distance which is larger than the hardcore distance. As in Raeisi et al. (2021), inference and simulation of the model were performed with logistic likelihood and birth-death Metropolis-Hasting algorithm, respectively. A multi-scale version of the model was introduced and applied to wildfires to take into account structural complexity of forest fire occurrences in space and time. We based our model validation on both pointwise and global envelopes and p -value based on the Extreme Rank Length (ERL) measure of the spatio-temporal inhomogeneous pair correlation function. Our model could be suitable in other environmental and ecological frameworks, when we want to deal with the complexity of mechanisms governing attraction and repulsion of entities (particles, cells, plants...).

In spatio-temporal Gibbs point process models, the heterogeneity can be captured by estimating a non-constant trend. This spatio-temporal trend is typically considered as a function of covariates by estimating fixed effects in a generalized linear model as we carried out it in this paper and also in Iftimi et al. (2018) and Raeisi et al. (2021). A different approach consists in considering Gibbs models with both random and fixed effects (e.g. see Illian and Hendrichsen, 2010) to take into account complex patterns of spatio-temporal heterogeneity. Vihrs et al. (2020) proposed a new modeling approach for this

case and embedded spatially structured Gaussian random effects in trend function of a pairwise interaction process. They introduced the spatial log-Gaussian Cox Strauss point process to capture both structures; aggregation in small-scale and repulsion in large-scale. Rather than spatial pairwise interaction processes in single-scale, we now focus on models derived from the multi-scale classes of combinations of Gibbs and log-Gaussian Cox point processes in space and time, to which we refer to as Cox-Gibbs models. We propose to embed spatio-temporally structured Gaussian random effects in the Gibbs trend function. Due to the hierarchical structure of such models, we can formulate and estimate them within a Bayesian hierarchical approach, using the INLA approach.
